CopperPlate Cooling Study

Synthetic acceptance fixture. This is not a real research paper.

Abstract
We compare a smoothing reconstruction method M with baseline B for copper plate temperature recovery. The pilot uses four development cases under one fixed random seed. The reported mean absolute error decreases by 12.5%. The experiment does not include an independent held-out evaluation.

Method
Method M adds a fixed smoothing step after baseline reconstruction. Both methods use the same four observations and objective. Settings were chosen using the development cases.

Evaluation
Table 1 on PDF page 2 reports average error and inference time on the same machine. The paper does not report per-case errors or repeated-seed variability.

Scope
These are preliminary development results. Code, data, and the smoothing coefficient are not provided in this fixture.

Results and limitations

Table 1. Four development cases; lower MAE is better.

Method	MAE (K)	Time (s)
Baseline B	8.0	2.0
Method M	7.0	6.0

All numbers are means over the same four development cases. No uncertainty interval is shown. Method M improves the reported MAE but increases inference time.

Limitations

The held-out accuracy and generalization to other plates remain unknown. The smoothing parameter was chosen using the same four cases. Reproduction requires the missing coefficient, code, and observations.

Conclusion

The pilot motivates further controlled evaluation; it does not establish generalization.
